# Photogrammetric Data Set, 1957-2000, and Bathymetric Measurements for Columbia Glacier, Alaska 

By Robert M. Krimmel

#### Abstract

Major changes in the length, speed, surface altitude, and calving rate of Columbia Glacier, Alaska have been recorded with stereo vertical photography acquired on 119 dates from 1957 to 2000. Photogrammetric analysis of this photographic record has resulted in precise measurement of these changes. From 1982 to 2000 Columbia Glacier retreated 12 kilometers, reduced its thickness by as much as 400 meters, increased its speed from about 5 to 30 meters per day, and increased its calving rate from 3 to 18 million cubic meters per day. All photogrammetric data for Columbia Glacier from 1957 to 2000 are included in this report, as well as supplemental data of ice-dammed lake surface levels, stagnant ice ablation rate, forebay bathymetry, ground control, and camera calibrations. These data are contained in 481 files, all preserved on a CD-ROM included with this report.

## INTRODUCTION

Columbia Glacier enters an inlet in northern Prince William Sound in south central Alaska about 20 kilometers (km) west of Port Valdez, Alaska (fig. 1). This tidewater glacier, about 1,100 square kilometers (km2) in area, has changed very rapidly since 1980, and rapid change contines to the date of this report. Icebergs produced when Columbia Glacier calves sometimes enter shipping lanes, tourism has developed around the glacier, and the rapid changes have generated scientific interest.

An important tool used in the studies of Columbia Glacier is aerial photography and associated photogrammetric measurements. The use of photogrammetry for Columbia Glacier measurements is described in Meier and others (1985).
Photogrammetric results for 1957-81 are given by Fountain (1982), and for 1982-92 by Krimmel (1987, 1992). The purpose of this report is to make available the existing photogrammetric data for Columbia Glacier that have not been previously published. In addition, data from the three earlier Columbia Glacier photogrammetric data reports are included in this report so that users of this material will have all data within one report. These previously published data are restricted to the point data only; neither the calculated nor gridded speed data are given. Data in this report require a modest level of programming resource to be fully utilized.

For illustrative purposes some Landsat satellite imagery (figs. 2, 3) is included in this report. Landsat has sufficient resolution to be useful in determining the terminus position, and for some instances can be used for speed measurements, but no attempt has been made to comprehensively include available Landsat or derived terminus positions or speeds in this report.

Ice dynamic modeling efforts, for which the material in this report is targeted, also require ice thickness data. For this reason the available water depth measurements in the forebay (which was ice filled when these data were initiated) are included. The water depth measurements are entirely independent of photogrammetry. These data are contained in 481 files, all preserved on a CD-ROM included with this report. This is the final report for the U.S. Geological Survey (USGS) portion of National Science Foundation grant OPP-9614505 awarded to the USGS and INSTAAR (University of Colorado).

## Coordinate System

The North American Datum of 1927 (NAD27), Universal Transverse Mercator (UTM) projection, zone 6 is used as horizontal reference. The National Geodetic Vertical Datum of 1929 is used as vertical reference, and may be referred to simply as "sea level".

A curvilinear coordinate system along the approximate center of the glacier, with 0 km (zero) at the head of the glacier (fig. 1) is used to describe locations along the center of the glacier. These locations are referred to by an "L" (for Longitudinal), followed by a number that gives the distance from the head of the glacier. For example, "L50" indicates a location near the centerline of the glacier 50 km from the head along the centerline.

The software associated with the analytical stereo plotter used to produce most of the data in this report calculated UTM coordinates to three decimal digits (millimeters). These "over-precise" numbers have been retained. Usually, $\mathrm{X}, \mathrm{Y}$, and Z values may be rounded to the nearest meter with no loss to the true precision. The six digit ( X ) and seven $\operatorname{digit}(\mathrm{Y})$ UTM characteristic values have been retained, but constants could be subtracted with no loss to the precision.

## Aerial Photography

Photographs used for the photogrammetric measurements given in this report were stereo vertical using 9 -inch film in calibrated cameras with a nominal focal length of 6 inches ( 150 mm ). Flight altitude ranged from $2,000 \mathrm{~m}$ to $9,000 \mathrm{~m}$, but the most frequent altitude was about $7,000 \mathrm{~m}$. The flight altitude was selected to give the coverage and detail needed. This usually required sufficient height that one photograph would span the width of the glacier and include ground control points on each side of the glacier. For some purposes multiple flight altitudes were used on the same day, which allowed ground control from the smaller scale photography to control more detailed larger scale photography that did not show any permanent control points. Photography prior to October 1991 was black and white, after which color (fig. 4) was sometimes used. Original negatives are in archives of the GeoData Center of the Geophysical Institute of the University of Alaska, Fairbanks, Alaska.

## Photogrammetric Analysis of the Photography

Diapositives (first generation positive contact reproductions on transparent plastic material) were used as the working medium for all photogrammetric measurements. The working diapositives with ground control, passpoint, and feature annotation are preserved. All the photogrammetric measurements reported by Krimmel (1992) and subsequent measurements were made by the author or people under his direct supervision. The methodology used for the photogrammetry was similar to that described by Meier and others (1985) with one major difference. The transfer of points (ground control and ice features) between different dates of photography that resulted in data described by Fountain (1982) and by Krimmel (1987), which included all the data referenced by Meier and others (1985), was made using different dates of photography on the respective sides of a stereo comparator with a floating point used for reference, and then marking the points with a $30-\mathrm{mm}$ drill. Instead, for this photogrammetry the "different date" points transferred using a method of superposition. The rotationally oriented through-lighted and magnified diapositives were shifted relative to each other until surface patterns coincided, and then the similar feature was marked on both diapositives using a third basal layer marked with a reference point (equivalent to the floating point). The earlier method and this method used the same information, but in a somewhat different way. In this method the diapositives were marked with a carefully sharpened straight pin, leaving a pit about 100 mm in diameter. This method depended on diapositives of similar scale and of similar emulsion density, both of which could be manipulated during the photographic reproduction process when necessary.

Mistakes may occur. During the process of following features from date to date, feature pairs are matched on the diapositives for each of the two dates. If the respective feature identification is confused, displacements may show errors of several hundred meters or more. These mistakes are usually very evident when displacements are converted to vectors, and are then corrected. A mistake may also occur when what is thought to be the same feature on respective dates, in fact is not. This type of mistake may be as much several hundred meters, in which case it can easily be seen and removed; or a few meters or less, in which case it would make a contribution to
measurement errors. The results were reviewed and obvious mistakes removed, but some may remain. Vectors that do not conform to nearby vectors should be suspect and may be removed from the data set. Mistakes are not considered to be errors.

Errors are inherent in photogrammetric methodology, and independently, in the identification of features in the sequential photography. An interior orientation corrects for systematic errors in lens and film distortion. A relative orientation corrects for earth curvature and refraction, and forms a 3-dimensional "model". The models are joined using SIMBA (Olsen, 1975), a photogrammetric block adjustment package, and then tied to ground control in an absolute orientation which results in residuals that can be used to estimate the photogrammetric accuracy of measured points relative to the ground. The residuals typically suggest a photogrammetric accuracy of $2-4 \mathrm{~m}$ in both the horizontal and vertical for well-defined points. Additional error is introduced during the identification of the same point on different dates. The features change between the flight dates because of ablation or snow accumulation and deformation, and change in sun angle may give features a different appearance. A somewhat subjective accuracy of 3 m in location was assigned to a well-defined point, and 4 m to the length of a displacement vector (which requires two location measurements, and the identification of the same point).

The software that is used for the photogrammetry yields values to the millimeter. In many of the tables and associated files, insignificant digits are retained.

## DATA ACQUIRED

Vertical aerial photography covering all or part of Columbia Glacier was obtained 119 times beginning in 1957 (117 times since mid 1976) until late 2000 (fig. 5, table 1). Nearly all of this photography was subjected to photogrammetric analysis, and whenever possible the terminus position, altitudes at some systematic grid of points, ice displacements from some previous photography date, area of glacier calved from the previous flight date, and the surface level of two icedammed lakes was measured.

## Terminus Positions

Numerous points are measured at the ice/water contact along the terminus (table 2). The connection of these points is a map of the terminus configuration. The terminus is not always definable because in some photographs it is difficult to determine where the ice has separated from the glacier. In that case, points are picked subjectively to make a continuous terminus configuration. A selection of these terminus configurations is shown on figure 6. The terminus position is reduced to a single number to represent the glacier length on the particular date by width averaging it along the active ice front. This is a subjective task despite attempts to be objective (Meier and others, 1985, p. F16; Krimmel, 1992, p. 4) as the glacier has changed, subsequent objective width-averaging methods have become obsolete and new ones have been be devised. Since 1992 a consistent width-averaging method was not used, but rather a subjective determination of glacier length relative to the previous terminus position has been made, and with reference to the $L$ points. The accuracy of the glacier length (table 1) is estimated to be 50 m , which is mainly because of contribution from the width-averaging system. Even with this large uncertainty, neither the long-term trend of a dramatically shortening (retreating) glacier nor the higher frequency length changes is lost (fig. 7).

Overlying the retreat trend is a cyclic length change in which advance is followed by greater retreat. This cyclic length change is assumed to be seasonally driven. A hand-drawn line though the time-length plot (fig. 7) approximates the length trend without the influence of the cyclic length change. This hand-drawn curve can be defined by x , y points along the line, producing a highly segmented line that can be subtracted from the measured lengths. The residual lengths, plotted as a function of the time of year along the abscissa (fig. 8) show a strong trend for a long (advanced) glacier in early summer, and a short (retreated) glacier in late fall or early winter. In an attempt to determine any change in the timing (within the year) or amplitude of the seasonal length change as the retreat has progressed, the residual lengths were divided into two periods: from 1975 through 1984, and from 1985 through 2000. A 4th degree polynomial, constrained to be periodic, was fit through both segments of values, which suggest that the time of maximum length has advanced from early June to early August, and the amplitude of the seasonal length change has increased by a factor of two.

## Altitudes

Surface altitude is easily measured when the surface is fractured with crevasses or is otherwise rough. The height of a "point" is never measured, but rather the measurement is to a surface of finite area. The area of the surface measured is a function of the photography scale, plotter magnification, surface stereo fusion, and the photogrammetrist. Typically, the surface area included in a height measurement at Columbia Glacier is a circle with poorly defined outer limits and about 15 m in diameter. The surface roughness is averaged within that area. The height measurements are ordinarily biased toward the top of the seracs rather than some distance into the crevasses.

An advantage of stereo photography is that the determination of a complete altitude field is theoretically possible. A common 2-dimensional display of an altitude field is a contour map. No attempt was made to create contour maps from any of the Columbia Glacier photography described in this report. Instead, measurement of height was confined to predetermined specific X, Y locations. All measurements carry $\mathrm{X}, \mathrm{Y}$, and Z values, but the $\mathrm{X}, \mathrm{Y}$ values always differ slightly from the $\mathrm{X}, \mathrm{Y}$ of the nominally defined point locations. This variation in X, Y never exceeds the 15 m diameter "window", and does not alter the subsequent analyses of the height data. The nominal X, Y locations were designed to allow the creation of a time series of height change in important zones, or along the centerline of the glacier. In an attempt to reduce the effect of surface roughness and measurement inaccuracy, clusters of nearby measurements were sometimes averaged. The locations of features used to measure displacements (discussed in the next section) also carry a $Z$ value that may also be used to determine the altitude field. However, the displacement features were not at consistent X, Y locations; thus it complicates analysis of the changing altitude field, and furthermore, these Z values were not specifically biased toward the serac tops.

Beginning in 1991, height measurements were made along transverse profiles at the L points (tables 3, $4 ; \underline{\text { fig. } 9) . ~ T h e ~ t r a n s v e r s e ~ p r o f i l e s ~ c o n s i s t e d ~ o f ~} 10$ points spaced at 100 m on a line normal to the centerline. From 1983 to 1991 heights were measured at $100-\mathrm{m}$ intervals in the east-west direction along UTM northings at 0.5 or 1.0 km intervals (Krimmel, 1992, p. 21-51). The 10 points of each of the 1991-2000 transverse profiles were averaged, and 10 points in
nearly equivalent areas from each of the 1983-91 measurements were averaged, and results are plotted for L 52 on figure 9. The long-term trend is for a thinning glacier. But the trend is by no means smooth-there are fluctuations within the thinning trend that are much larger than the measurement inaccuracies. The long-term thinning trend was removed by assuming that these fluctuations are driven seasonally and applying a method similar to that used with that glacier length time series (fig. 10). This suggests, but perhaps only marginally, that the glacier is thicker in early spring and thinner in the fall. The long-term height change over the entire length of the glacier is shown on figure 11. Near the receding terminus (wherever it may be) the height decreases about 20 m per year.

An area was picked where the ice had stagnated as the glacier retreated (shown as A on fig. 6). Within this area ice flow was negligible. A grid of 20 nominal $\mathrm{X}, \mathrm{Y}$ points was established, and heights were measured on a series of late summer or early fall dates. The rate of change in the average height of all the points within the grid on each date represents the annual ice ablation (the net balance at that point) of about 9 m per year between 1983 and 1996 (fig. 12).

## Displacements

In many areas the general appearance of the serac/crevasse patterns is preserved for several months, or even years, and is carried along with the flowing ice. Specific crevasses or seracs can be followed, date to date, and their locations measured on both dates. Depending mainly on the length of interval and region of the glacier, the density of displacement measurements may range from 1 to 20 per km 2 , with resulting vectors from a few meters to a few kilometers in length. An example of displacement vectors is shown on figure 13. The interval shown on figure 13 (August 13, 1994, to September 7, 1994) was short enough that displacements of icebergs in the brash matrix of the forebay could also be measured. The location of the measurements (table 5), that is, the end point of either end of the vector, was not consistent from flight interval to interval. Instead enough measurements were made so that displacements for specific locations could be interpolated from nearby locations. This interpolation was normally done using the derived speed vectors (table 6). As an example,
interpolated speeds at L50 from 1977 to 1997 are shown on figure 14, where the large increase in speed over the time period is obvious. As with the terminus and the height data, the long-term speed increase can be removed, leaving speed deviations, separated into the periods 1977 though 1984 and 1985 through 1997, which are assumed to be seasonally cyclic. They are plotted on figure 15 and suggest high speed in spring and low speed in fall. Seasonal speed changes have continued this cyclic trend throughout the retreat, but with an increase in amplitude as the retreat has progressed. The fit curves on figure 15 are 3rd degree polynomials, not constrained to be periodic. The longterm speed change is plotted on figure 16.

The measurements that are used for displacements include a Z value, which may be useful for determining the vertical displacement of the ice, but those Z values are less reliable than those measurements made specifically for height.

## Lake Levels

The water level of ice-dammed Terentiev Lake (adjacent to L62) and Kadin Lake (adjacent to L54) fluctuated during the terminus retreat through the forebay (see fig. 1 for locations). Few data exist prior to 1976, but presumably the lake levels were either stable or had periodic outbursts followed by refill to approximately the previous level. During the retreat both lakes had numerous outbursts, followed by subsequent refilling. By 1992 the Terentiev Lake level had stabilized at 13 m and will likely remain a freshwater lake, and by 2000 the Kadin Lake level had reached a low level of 15 m , but because ice still covered the outlet the lowest possible level is unknown. The fill-outburst cycles of both lakes had a lowering trend during the retreat, with a lowering of about 8.5 m per year_(fig. 17).

## Bathymetry

During the period when most of the speed and surface altitude measurements were made, the ice thickness and fiord bottom topography were unknown, or at best were inferred from radar (Brown and others, 1986) or modeling efforts (Rasmussen, 1989).

Prevalent icebergs and compact brash ice in the forebay prevented the use of boat or helicopter-borne
fathometers. In late summer or fall of 1995, 1996, and 1997 the forebay became mostly clear of floating ice, and a boat-borne fathometer was used to measure water depth at numerous discrete places to within a few hundred meters of the terminus ice cliff. No satisfactory explanation for the relatively ice-free forebay during those times is known.

A generalization of the bathymetry data is shown on figure 18, where contours are used to represent the forebay bottom. The contours were formed automatically using a $200-\mathrm{m}$ grid formed using the Kriging method. Dots on figure 18 indicate the position of soundings. Users of these data should not rely on figure 18, but rather should refer to the entire bathymetric data set prior to any rigorous application.

## Calving

The ice lost by calving at the terminus could sometimes be measured directly between flight dates. This required that the ice at the terminus on the second date be identified on the first date. This allowed the "ice-to-be-calved" to be surrounded by numerous points along the perimeter, that is, the top of the ice cliff at the terminus and an irregular line some distance up glacier from the terminus (fig. 19). This procedure was possible for most intervals from 1978-94. An example of an "ice-to-be-calved" file is shown in table 7.

The thickness of the "ice-to-be-calved" was taken as the average Z of all the perimeter points added to the average of all the gridded bathymetric values that were under the upper surface. The calved volume was taken to be the thickness times the number of $200-\mathrm{m}$ grid points times $40,000 \mathrm{~m} 2$. Rate of calving is plotted on figure 20. The rate of calving has increased by a factor of 6 since the retreat began. The assumed seasonal cycle in the rate of calving is determined in a fashion similar to that of seasonal cycles in glacier length and speed, and if anything, is greater in the fall and reduced in the spring (fig. 21). The seasonal maximum rate of calving has tended to become later in the fall, with an increased magnitude between minimum and maximum rate as the retreat has progressed. The pre-1985 and post-1986 curves (fig. 21) are both unstrained 3rd degree polynomials.

## DATA FILES AND STORAGE

The fundamental data are the photographic negatives. Data extracted from the stereo photography are preserved on optically readable medium, that being a CD-ROM formatted for MS Windows operation systems, a copy of which is included with this report. All files, except for images and the report text, are space-delimited ASCII. Any software capable of importing an ASCII text file should be able to read these files. No software is included in this report or on the CD-ROM.

All files are in one directory. The file names describe the file contents, thus it is important that files are not renamed without first somehow identifying the contents. Files were named with no systematic use of letter case. In the originating operating system (MSDOS) the letter case was ignored. Some operating systems may require a specific letter case, which may be determined by trial. The file structure, content, and names evolved though the period of this work and no attempt was made to improve upon these (other than to assure consistency). The stereo plotter software gave a line-by-line output that included four values: an integer identification which could be manually set, a real x , a real $y$, and a real $z$. The integer identification was retained even when it is meaningless.

Files with names of the form nnnT, where nnn is the flight number, contain terminus position data. Each file is in the form: $\mathrm{C} 1=$ an integer value of no use, $\mathrm{C} 2=$ a real value of UTM X, C3 $=$ a real value of UTM Y , and $\mathrm{C} 4=$ a real value, usually near zero, of little use. Table 8 lists these files. No file exists for flight 078 because photogrammetry was never done on this flight, which was 2 days after flight 077, or for flight 110 because the quality was poor. Files for flights 075 and earlier are identical to those of Fountain, 1982, and Krimmel, 1987 and 1992.

Files with names of the form nnnP (table 9), where nnn is the flight number, are surface altitude data along profiles that also appeared in Krimmel, 1992 (Appendix 1). Each file is in the form of: $\mathrm{C} 1=$ a three or four digit integer number. The three digits, or if a four digit number, then the first three digits, is the central three digits in the seven digit UTM northing. If there is a fourth digit, a " 1 " indicates that the point is at the east or west end of the profile; if the fourth digit is a " 0 ", it is a point along the profile but beyond the edge of the glacier. C2 $=$ UTM X, C3 $=$ UTM Y, and C4 $=\mathrm{Z}$.

File KMALT is a large file and includes all the
altitude data taken at the specific profile points (table 3 is an example of the points). In this file $\mathrm{C} 1=$ flight number, $\mathrm{C} 2=\mathrm{UTM} \mathrm{X}, \mathrm{C} 3=\mathrm{UTM} \mathrm{Y}$, and $\mathrm{C} 4=\mathrm{Z}$. Table 9 gives the flight numbers for which these data were taken, and the number of points on each of those flight dates. For some dates and profiles redundant data exist because the same profile was measured on adjacent stereo models. Table 4 is a sample of these data.

Files with names of the form aaaV-bbb, bbbVaaa (table 10), where aaa and bbb are the flight numbers, contain positions of points used for displacements; aaa is the number of the first flight and bbb is the number of the second flight. A few of these file names carry a single letter extension that is used when additional flight lines (for instance, for additional coverage or at a different scale) are flown on the same day and carry the same flight number. Table 5 is a portion of one of these files to show a sample of the file contents. Each file is in the form: $\mathrm{C} 1=$ an integer value that identifies the point, the equivalent point number is used in the subsequent (or preceding) flight, $\mathrm{C} 2=$ a real value of UTM X, C3 $=$ a real value of UTM Y, C4 = a real value of Z . These files always occur in pairs; for instance, file $085 \mathrm{~V}-086$ contains the first location of points used to measure displacements from flight 085 to 086 and file $086 \mathrm{v}-085$ contains the second location of points used to measure displacements from flight 085 to 086. The flight numbers, are usually, but not always, consecutive. Files with names of the form Gnnn, where nnn is a flight number are of points used for displacement prior to flight 036 and are of the form: $\mathrm{C} 1=\mathrm{a}$ integer giving a point identification that is unique to a particular point from the first date on which it is located until it was no longer found on subsequent flight dates. When a point is lost, the same number may be used again on later dates. C2 $=$ a real value of UTM $\mathrm{X}, \mathrm{C} 3=$ a real value of UTM Y, and $\mathrm{C} 4=\mathrm{Z}$. Files for flight 075 and earlier are identical to those of Fountain, 1982, and Krimmel, 1987 and 1992.

Files of the form Vaaa-bbb (table 11), where aaa and bbb are the flight numbers, contain velocity data for the indicated interval. Table 6 is a portion of one of these files as an example of the file content. These data are derived from the respective pairs of aaaV-bbb and bbbV-aaa files. The file columns are defined in table 6. A few of these file names carry a single letter extension which is used when additional flight lines (for instance for additional coverage or at a different scale) flown on the same day and carry the same flight number. These
velocity data are presented to demonstrate the high ice speeds at Columbia Glacier. Users of these data may wish to derive their own velocity files, in different formats or with different output, from the respective displacement files.

Files of the form nnnC (table 12), where nnn is the flight number, are "ice-to-be-calved" files. The flight number is the first of the pair of flight dates required. The interval is always to the next flight, but with one exception: file 077C is the "ice-to-be-calved" from flight 077 to flight 079 . Table 7 is a portion of one of these files as an example of the file content. Each of the nnnC files is in the form: $\mathrm{C} 1=$ an integer value of no use, $\mathrm{C} 2=$ a real value of UTM $\mathrm{X}, \mathrm{C} 3=$ a real value of UTM Y, and C4 $=$ a real value of Z . These $\mathrm{X}, \mathrm{Y}$ points form the perimeter of the "ice-to-be-calved" (see fig. 19). The $Z$ values are measured to an average upper ice surface.

Files KMPTS, ABLATION, LKLEV, BATH, BATHGRID, CONTPTS, and CAMFILES are one of a kind, and are described in the next paragraphs. Each of these files contains header information describing its contents.

File KMPTS contains the nominal point locations for the altitude profiles used beginning in 1991 (the locations of altitudes given in file KMALT).

File ABLATION is the ice surface level in a stagnant ice area (box A on figure 6) on several dates.

File LKLEV is the surface level of Terentiev and Kadin Lakes.

File BATH contains all the bathymetric measurements from Columbia forebay.

File BATHGRID contains the bathymetric measurements from BATH gridded to a $200-\mathrm{m}$ grid using a Kriging method.

File CONTPTS contains the ground control used in the photogrammetry.

File CAMFILES contains all available camera calibration reports used for the photogrammetry discussed in this report. Individual calibration reports (table 1) may be extracted from this text file. Table 1 references a calibration report for each flight.

The files with an extension of .tif are similar to the cover photograph and figures 2-4. File TEXT.doc is a MS word file containing the text of the report.

## OTHER SOURCES FOR THESE DATA TYPES

Terminus position may be recorded by any good observer with a good vantage and camera. Commercial air traffic routes offer pilots and passengers good views of the terminus of Columbia Glacier on days with clear weather. Charter and private aircraft are also frequently in the vicinity of the terminus. Certainly many photographs exist that would serve to help map the terminus between the times of the vertical photography described in this report. No solicitation for such photographs were made, nor were the USGS files perused for random photographs of this type.

Space-borne radar, which has capability of observation when clouds prevent visible light viewing and during dark, often has resolution sufficient to show the terminus position of Columbia Glacier, but no effort has been made for this report to find the existing imagery. The Landsat series of satellites is restricted to observations during daylight and fair weather and also has sufficient resolution for useful terminus recording. The early Landsats were with a $80-\mathrm{m}$ pixel, and of limited use at Columbia Glacier. With the advent of 30m pixel size, or $15-\mathrm{m}$ with Landsat 7 , the terminus can easily be mapped. An exhaustive search for available satellite data was not intended, but a portion of a 1978 image from the short-lived Return Beam Vidicon Sensor (fig. 2) and one Landsat 7 image (fig. 3) were included.

## CONCLUSIONS

Aerial photography and subsequent photogrammetric measurements have proven to be a very practical method to obtain extensive data concerning the static and dynamic geometry of Columbia Glacier.

Although it is not the intent of this report to determine processes that cause these changes in Columbia Glacier, I will go beyond a presentation of raw and condensed data and point out possible causes of some of the observations.

Changes in the terminus position (the glacier length) are an easy observation to make but are not an important consideration in the process of the changes, but rather, are only a consequence of speed and calving. The seasonal changes in glacier length are a result of seasonal changes in speed and calving.

Feedback from the terminus position may be important to the dynamics, if for instance, changing length resulted in changing basal drag. Likewise, changing height is a consequence only of changing glacier length-the mechanical properties of ice do not allow a terminal ice cliff several hundred meters high. The seasonal changes in height are caused by winter snow and summer ablation, or possibly dynamics effects. Feedback from the changes in ice thickness may be important because of resulting changes in pressure on the bed. The thinning of the glacier in the active areas ( 20 m or more per year) is much greater than in stagnant areas ( 9 m per year). Ice ablation rate (see fig. 12) and the general trend of the lowering of Terentiev and Kadin Lakes (see fig. 17) were all very similar to each other, suggesting a simple ice thickness control of the lake levels. Ablation area thinning from 1957-74 was a few meters or less, which suggests that the glacier was in climatic equilibrium for at least 2 decades prior to the onset of the rapid retreat: that is, the ice emergence term nearly matched the net balance.

This data set is large and complex. In its purest form it can be reduced to the original film negatives. The negatives represent the condition of the glacier at an instant in time, and of course, the time series of negatives represents a time series of the glacier conditions. By adding photogrammetric analysis of this photographic record, the time series can be described numerically. Only a small portion of the information that is inherent in the photography has been extracted. Additional displacement data, and particularly additional height data, could be extracted, perhaps best by the automated methods that have come into use in the 1990's. Interpretations made here are not intended to be the "last word"-new and better interpretations may be made and are welcomed. For example, a different approach to the width-averaging problem could result in a significantly different length-time function and suggest new retreat mechanisms; or by resegmenting the time-dependent length, height, speed, and calving records, different shifts in the assumed seasonal patterns and amplitudes may become evident.

This photographic record is the longest and most detailed that exists for any tidewater glacier, and because we cannot revisit the past, but rather rely only on records from the past, will become more valuable as
it ages. If Columbia Glacier ultimately retreats through its fiord completely, and the fiord bed is mapped, then future generations of glaciologists will have a rich data set of glacier geometry and dynamics to model. It is my hope that this photographic data set and data in this report, or additionally extracted data, will be the impetus for that use, and may play a part in answering major questions concerning past, present, and future ice sheet stability.

## FIGURES

Figure 1. Columbia Glacier, Alaska.
[Broad arrows show approximate direction of flow, numerals near solid circles (L points) indicate the distance from head of glacier along the centerline, in kilometers, dashed box indicates the lower reach area over which the aerial photography was concentrated.]

Figure 2. Columbia Glacier as imaged by Landsat Return Beam Vidicon (RBV) on August 26, 1978.

Figure 3. Columbia Glacier as imaged by Landsat Thematic Mapper (TM) on September 26, 1999.
Vegetation appears red in this false color band combination. Note the change in the medial moraines between 1978 (figure 2) and 1999 near the image center.

Figure 4. Vertical photographic mosaic of a portion of Columbia Glacier, September 18, 2000

Figure 5. Columbia Glacier vertical photography flights.
The flight numbers are shown at the time within the year indicated along the abscissa.

Figure 6. Selected Columbia Glacier terminus positions from 1974-2000. Box A indicates the area used in an ablation study. Glacier outline is from 1974.
t

Figure 7. Columbia Glacier width-averaged length from 1976-2000.
The solid circles indicate the length and the open circles are points along the indicated hand-drawn curve. Year ticks indicate January 1.

Figure 8. Seasonal deviations in the length of Columbia Glacier, as measured from the hand-drawn curve shown on figure 7.
The length deviation for each flight date is shown on the ordinate, the time of year for each flight date is shown on the abscissa. Circles are for flights from 1875-84, dashed line is the fit curve ( $r^{2}=0.409$ ). Dots are for flights after 1984, black line is the fit curve ( $r^{2}=0.516$ ).

Figure 9. Columbia Glacier surface altitudes at L52 on flight dates from 1983-2000.
Solid circles indicate altitude on each date, open circles are points along the indicated hand-drawn curve. Year ticks indicate January 1.

Figure 10. Seasonal height deviations at L 52 on Columbia Glacier, as measured form the hand-drawn curve shown on figure 9 .
The height deviation of reach flight date is shown on the ordinate, the time of year for each flight data is shown on the abscissa. The solid line is a 3rd degree polynomial fit through the points, and with an $r^{2}$ of 0.08 and may not be statistically significant.

Figure 11. Height change of Columbia Glacier surface along the centerline.
The 1950 and 1974 profiles were nearly the same. By 1982, the surface began to depress rapidly. the bed is measured form L58 t0 L68, and estimated by modeling and a borehole along the remaining distance upglacier.

Figure 12. Surface lowering in a stagnant ice area of the lower Columbia Glacier.
Circles are averages of the points in a 20-point grid (A on figure 6) on each date measured. The heavy line is the linear trend after ice stagnation occurred. year ticks indicate January 1.

Figure 13. Columbia Glacier surface displacements for the interval August 13 to September 7, 1994 (flights 88-89).
Arrow tail is at flight 88 position, arrow head is at flight 89 position. Arrows may show an erroneous direction when the movement was less than a few meters. Displacements in the forebay are that of the floating ice mass.

Figure 14. Speed at the L50 point on Columbia Glacier, 1977-97.
Solid circles indicate the speed during each flight interval, open circles are points along the indicated hand-drawn curve. Year ticks indicate January 1.

Figure 15. Seasonal speed deviations at L50, as measured from the hand-drawn curve shown on figure 14.
The speed deviation for each flight interval is shown on the ordinate, the time of year for each flight date is shown on the abscissa. Circles are for intervals from 1978-84, and dots are for intervals after 1984. The dashed line is a 3rd degree polynomial fit through the former points with an $r^{2}$ of 0.759 and the black line is a 3rd degree polynomial fit through the latter points with an $r^{2}$ of 0.670 .

Figure 16. Annual speed of Columbia Glacier along centerline for measurement years (September through the following August) 1978, 1993, and 1999.

Figure 17. Level of Kadin and Terentiev Lakes near Columbia Glacier (see figure 1 for locations).
The dashed lines are the linear trend over the years spanned by the line. Year ticks indicate January 1.

Figure 18. Bathymetric measurement locations and contours of water depth in Columbia Glacier forebay.
Each dot is a sounding location, the contours are in meters of water depth.

Figure 19. Columbia Glacier "ice-to-calved" for the epoch from August 13 to September 7, 1984 (flights 88-89).
The volume of "ice-to-be-calved" is taken as the area times the average of the gridded bathymetric measurements included within the area plus the average height of the surface perimeter points.

Figure 20. Calving rate at Columbia Glacier 1976-95.
Solid circles indicate the calving rate during each flight interval, open circles are points along the indicated hand-drawn curve. Year ticks indicate January 1.

Figure 21. Seasonal calving rate deviations for Columbia Glacier, as measured from the hand drawn curve on figure 20. The calving rate deviation for each flight interval is shown on the ordinate, the time of year for each flight date is shown on the abscissa. Circles are for intervals from 1977-84, dots are for intervals after 1984. The dashed line is a 3rd degree polynomial fit through the former points with an $r^{2}$ of 0.158 , and the black line is a 3rd degree polynomial fit through the latter points with an $r^{2}$ of 0.585 .

1
solar year, or the time between two successive vernal equinoxes. The value of $t$ shown for each flight refers to noon local civil time on the indicated date.
Where $\mathrm{D}=1$ on 1 JAN 78, and increases by 1 for each day thereafter, then $t=1977.99863+0.00273791 D$ gives the value of $t$ at noon local civil time on the date corresponding to D . The cumulative effect of the annual variation of the length of the day from local true solar noon to local true solar noon) never exceeds 0.00003 solar year (Flamarrion, 1880).
${ }^{2} \mathrm{a}=$ most of glacier;
$\mathrm{b}=$ whole glacier;
c $=$ lowest 4 km ;
$\mathrm{d}=$ lower reach;
$\mathrm{e}=$ icefall reach;
$\mathrm{f}=$ central basin;
$\mathrm{g}=$ very poor quality;
$\mathrm{h}=$ color;
$\mathrm{o}=$ oblique included;
$\mathrm{t}=$ terminus only;
$\mathrm{np}=$ no photogrammetry on this flight;
tp $=$ terminus poorly defined.
${ }^{3}$ The glacier length (flights 1-62) is measured along a curvilinear centerline of the main branch as shown on figure 1 of Meier and others (1985). The terminus position is width averaged using a curvilinear Xi-Zeta grid as drawn by Meier (unpublished) during the early part of the USGS Columbia Glacier project. For flights $63-79$ the length is width averaged between UTM $x=496500$ and UTM $x=499000$. Length after flight 79 was subjectively measured relative to the previous flight, referenced to the L points. Error in the glacier length is estimated to be 0.04 km .
${ }^{4}$ The camera files are give in the file CAMFILES on the CD-ROM in the pocket at the end of the report.

Table 2. An example of positions along the Columbia Glacier ice-water interface from the terminus file, in UTM eastings and northings, a portion of the file for 13AUG94

# Table 6. A sampling of Columbia Glacier speed 

[Derived speed from point locations on 13AUG94 and 07SEP94, a 25-day interval. Directions in degrees, counter clockwise from south; ID, identification; UTM, Universal Transverse Mercator]

Table 7. A sampling of Columbia Glacier "ice-to-be-calved" (File 088C)
[Ice was calved between 13AUG94 and 07SEP94, and the area of this ice can be delimited as a polygonal shape that is the top of the terminal ice cliff on the first date and a superposition of the ice very near the terminal ice cliff on the second date on the first date. UTM, Universal Transverse Mercator]
