Environmental Characteristics and Geographic Information System Applications for the Development of Nutrient Thresholds in Oklahoma Streams

By Jason R. Masoner, Brian E. Haggard, and Alan Rea

Abstract

The U.S. Environmental Protection Agency has developed nutrient criteria using ecoregions to manage and protect rivers and streams in the United States. Individual states and tribes are encouraged by the U.S. Environmental Protection Agency to modify or improve upon the ecoregion approach. The Oklahoma Water Resources Board uses a dichotomous process that stratifies streams using environmental characteristics such as stream order and stream slope. This process is called the Use Support Assessment Protocols, subchapter 15. The Use Support Assessment Protocols can be used to identify streams threatened by excessive amounts of nutrients, dependant upon a beneficial use designation for each stream. The Use Support Assessment Protocols, subchapter 15 uses nutrient and environmental characteristic thresholds developed from a study conducted in the Netherlands, but the Oklahoma Water Resources Board wants to modify the thresholds to reflect hydrologic and ecological conditions relevant to Oklahoma streams and rivers.

Environmental characteristics thought to affect impairment from nutrient concentrations in Oklahoma streams and rivers were determined for 798 water-quality sites in Oklahoma. Nutrient, chlorophyll, water-properties, and location data were retrieved from the U.S. Environmental Protection Agency STORET database including data from the U.S. Geological Survey, Oklahoma Conservation Commission, and Oklahoma Water Resources Board. Drainage-basin area, stream order, stream slope, and land-use proportions were determined for each site using a Geographic Information System. The methods, procedures, and data sets used to determine the environmental characteristics are described.

Introduction

The U.S. Environmental Protection Agency has developed nutrient criteria using ecoregions to manage and protect rivers and streams in the United States from impairment (Robertson, Saad, and Wieben, 2001). Individual states and tribes are encouraged by the U.S. Environmental Protection Agency to modify or improve upon the ecoregion approach. (Robertson, Saad, and Wieben, 2001). The Oklahoma Water Resources Board (OWRB) developed a dichotomous process that stratifies or groups streams using environmental characteristics such as

stream order and stream slope to identify streams that need further study to determine if they are impaired (OWRB, 2001). This process is called the Use Support Assessment Protocols, subchapter 15 (USAP). The OWRB is using nutrient and environmental characteristic thresholds developed in the Netherlands (Peters and Gardeniers, 1998; OWRB, 2001). The USAP can be used to identify streams threatened by excessive amounts of nutrients, dependant upon a beneficial use designation for each stream. Nutrient criteria are not synonymous with water-quality standards. The purpose of the USAP is to identify streams, based on nutrient and environmental characteristic thresholds for each stream, that may be threatened by excessive amounts of nutrients and impairment of their beneficial use. Further studies would be required to determine if water-quality standards are exceeded.

The U.S. Geological Survey, in cooperation with the Oklahoma Water Resources Board, is providing descriptive statistics of water-quality sampling sites that can be used to modify the USAP to reflect hydrological and ecological conditions relevant to Oklahoma streams and rivers. Four environmental characteristics -- drainage-basin area, stream order, stream slope, and land-use proportions -- that affect nutrient concentrations in Oklahoma streams were compiled using a Geographic Information System (GIS) and are provided in appendix 1 (back of report). These characteristics, when used in conjunction with water-quality data collected from Federal, State, tribal, and local programs, will help evaluate streams in Oklahoma and through statistical models, help determine which streams are nutrient threatened.

Purpose and Scope

This report describes the methods, procedures, and data sets used to determine environmental characteristics and provides a list of the environmental characteristics (appendix 1, back of report) that can be used to help modify the USAP thresholds to represent hydrological and ecological conditions relevant to streams in Oklahoma. Nutrient, chlorophyll, water-properties, and location data were retrieved for 798 water-quality sites from the U. S. Environmental Protection Agency STORET database (U.S. Environmental Protection Agency, 2001), the Oklahoma Conservation Commission, and the Oklahoma Water Resources Board. STORET included data collected by the U.S. Geological Survey.

2 Environmental Characteristics and Geographic Information System Applications for the Development of Nutrient Thresholds in Oklahoma Streams

The 798 water-quality sites are located in Oklahoma, but the geographic scope of the data sets used to derive environmental characteristics included the Arkansas-Red River drainage basins, an area of about 202,000 square miles (fig. 1). There are many sampling sites listed in appendix 1 that are reported as having different site identification numbers but have identical latitude and longitude coordinates. This is because there are multiple federal and state agencies collecting and maintaining independent water-quality databases that use different procedures for designating site identification numbers. This report provides environmental characteristics for each water-quality site so that the agencies responsible for maintaining a particular site would have access to environmental characteristics through the site identification number. The water-quality sites are not labeled on figure 1, as many of the sites are extremely close together and the purpose of this report is to provide the environmental characteristics and to describe the methods, procedures, and data sets used to determine the environmental characteristics.

Acknowledgments

The authors thank Robert Tortorelli, Evan Hornig, and Lyn Osburn of the U.S. Geological Survey for their contributions to this report.

Environmental Characteristics and GIS Applications

Drainage-basin areas

Drainage-basin areas for 798 water-quality sites in Oklahoma were determined from several data sources using ARC/INFO (ESRI, 2001a) and ARC/VIEW (ESRI, 2001b) GIS applications. Topographic data sets of flow direction and flow accumulation were used to delineate drainage basins. Flow-direction and flow-accumulation data sets were created from a hydrologically conditioned Digital Elevation Model (DEM) with a 60-meter cell size. The DEM was created from elevation data (hypsotherapy) and stream data (hydrography) from digital versions of the U.S. Geological Survey 1:100,000-scale topographic maps (Cederstrand and Rea, 1995).

Development of flow-direction and flow-accumulation data sets is an important step in delineating drainage basins using DEMs. A flow-direction data set (fig. 2) contains cell values that indicate the direction water will flow out of each cell based on elevation (Jenson and Domingue, 1988). A coding structure developed by Jenson and Domingue, (1988) codes cells based on the orientation with respect to one of the eight neighboring cells. The coding structure uses slope calculations between neighboring cells to code individual cells. Slope is calculated from the change in elevation between cells divided by the distance between cell centers. The distance between cell

centers for diagonal cells is measured by multiplying the cell size by the square root of two.

The flow accumulation grid (fig. 3) contains cell values computed from the flow direction grid that equal the number of cells that flow into it. Cells having a flow accumulation value of zero (to which no other cells flow) generally correspond to the pattern of ridges (Jenson and Domingue, 1988). Cells that have many other cells flowing into it usually are representative of streams or rivers.

The ARC/INFO GRID module was used to delineate drainage basins and compute corresponding basin areas (ESRI, 2001a). Individual water-quality sites were used to define a pour point (an outlet for a drainage area) from which a complete or partial drainage basin was created. An automated process was developed that iteratively selected a water-quality site, converted it into a pour point, snapped the pour point to cells of high flow-accumulation, and delineated a drainage basin for that site. The RESELECT command selected a single water-quality site and the POINTGRID command converted the point into a grid point. The SNAPPOUR command adjusted the points to cells of high flow accumulation and the WATERSHED function delineated the drainage area using the flow-accumulation and flow-direction data sets.

A partial drainage basin was created when the drainage basin for a water-quality site extended beyond the coverage of the flow-direction and flow-accumulation data sets of Cederstrand and Rea (1995), which were limited to a small margin around Oklahoma. Additional techniques using the ARC/VIEW GEOPROCESSING (ESRI, 2001b) extension were used to complete drainage basins. Partial drainage basins were completed by appending the most detailed digital hydrologic unit maps available for that area. Two hydrologic unit data sets, Seaber and others (1984) and Kansas Data Access and Support Center (2000), were used to complete partially defined drainage basins. The UNION operation appended the partially defined drainage basin and the hydrologic unit maps. The DISSOLVE operation eliminated small sliver polygons created from the UNION operation. This method resulted in one polygon unit that represented the drainage-basin area. Drainage-basin areas for each water-quality site are listed in appendix 1 (back of report).

Stream Order

Stream order was calculated using methods developed by Strahler (1952) and a stream data set created from a hydrologic derivative (flow accumulation) of the U.S. Geological Survey National Elevation Dataset (NED). NED is spatially referenced in a geographic coordinate system using degrees, minutes, and

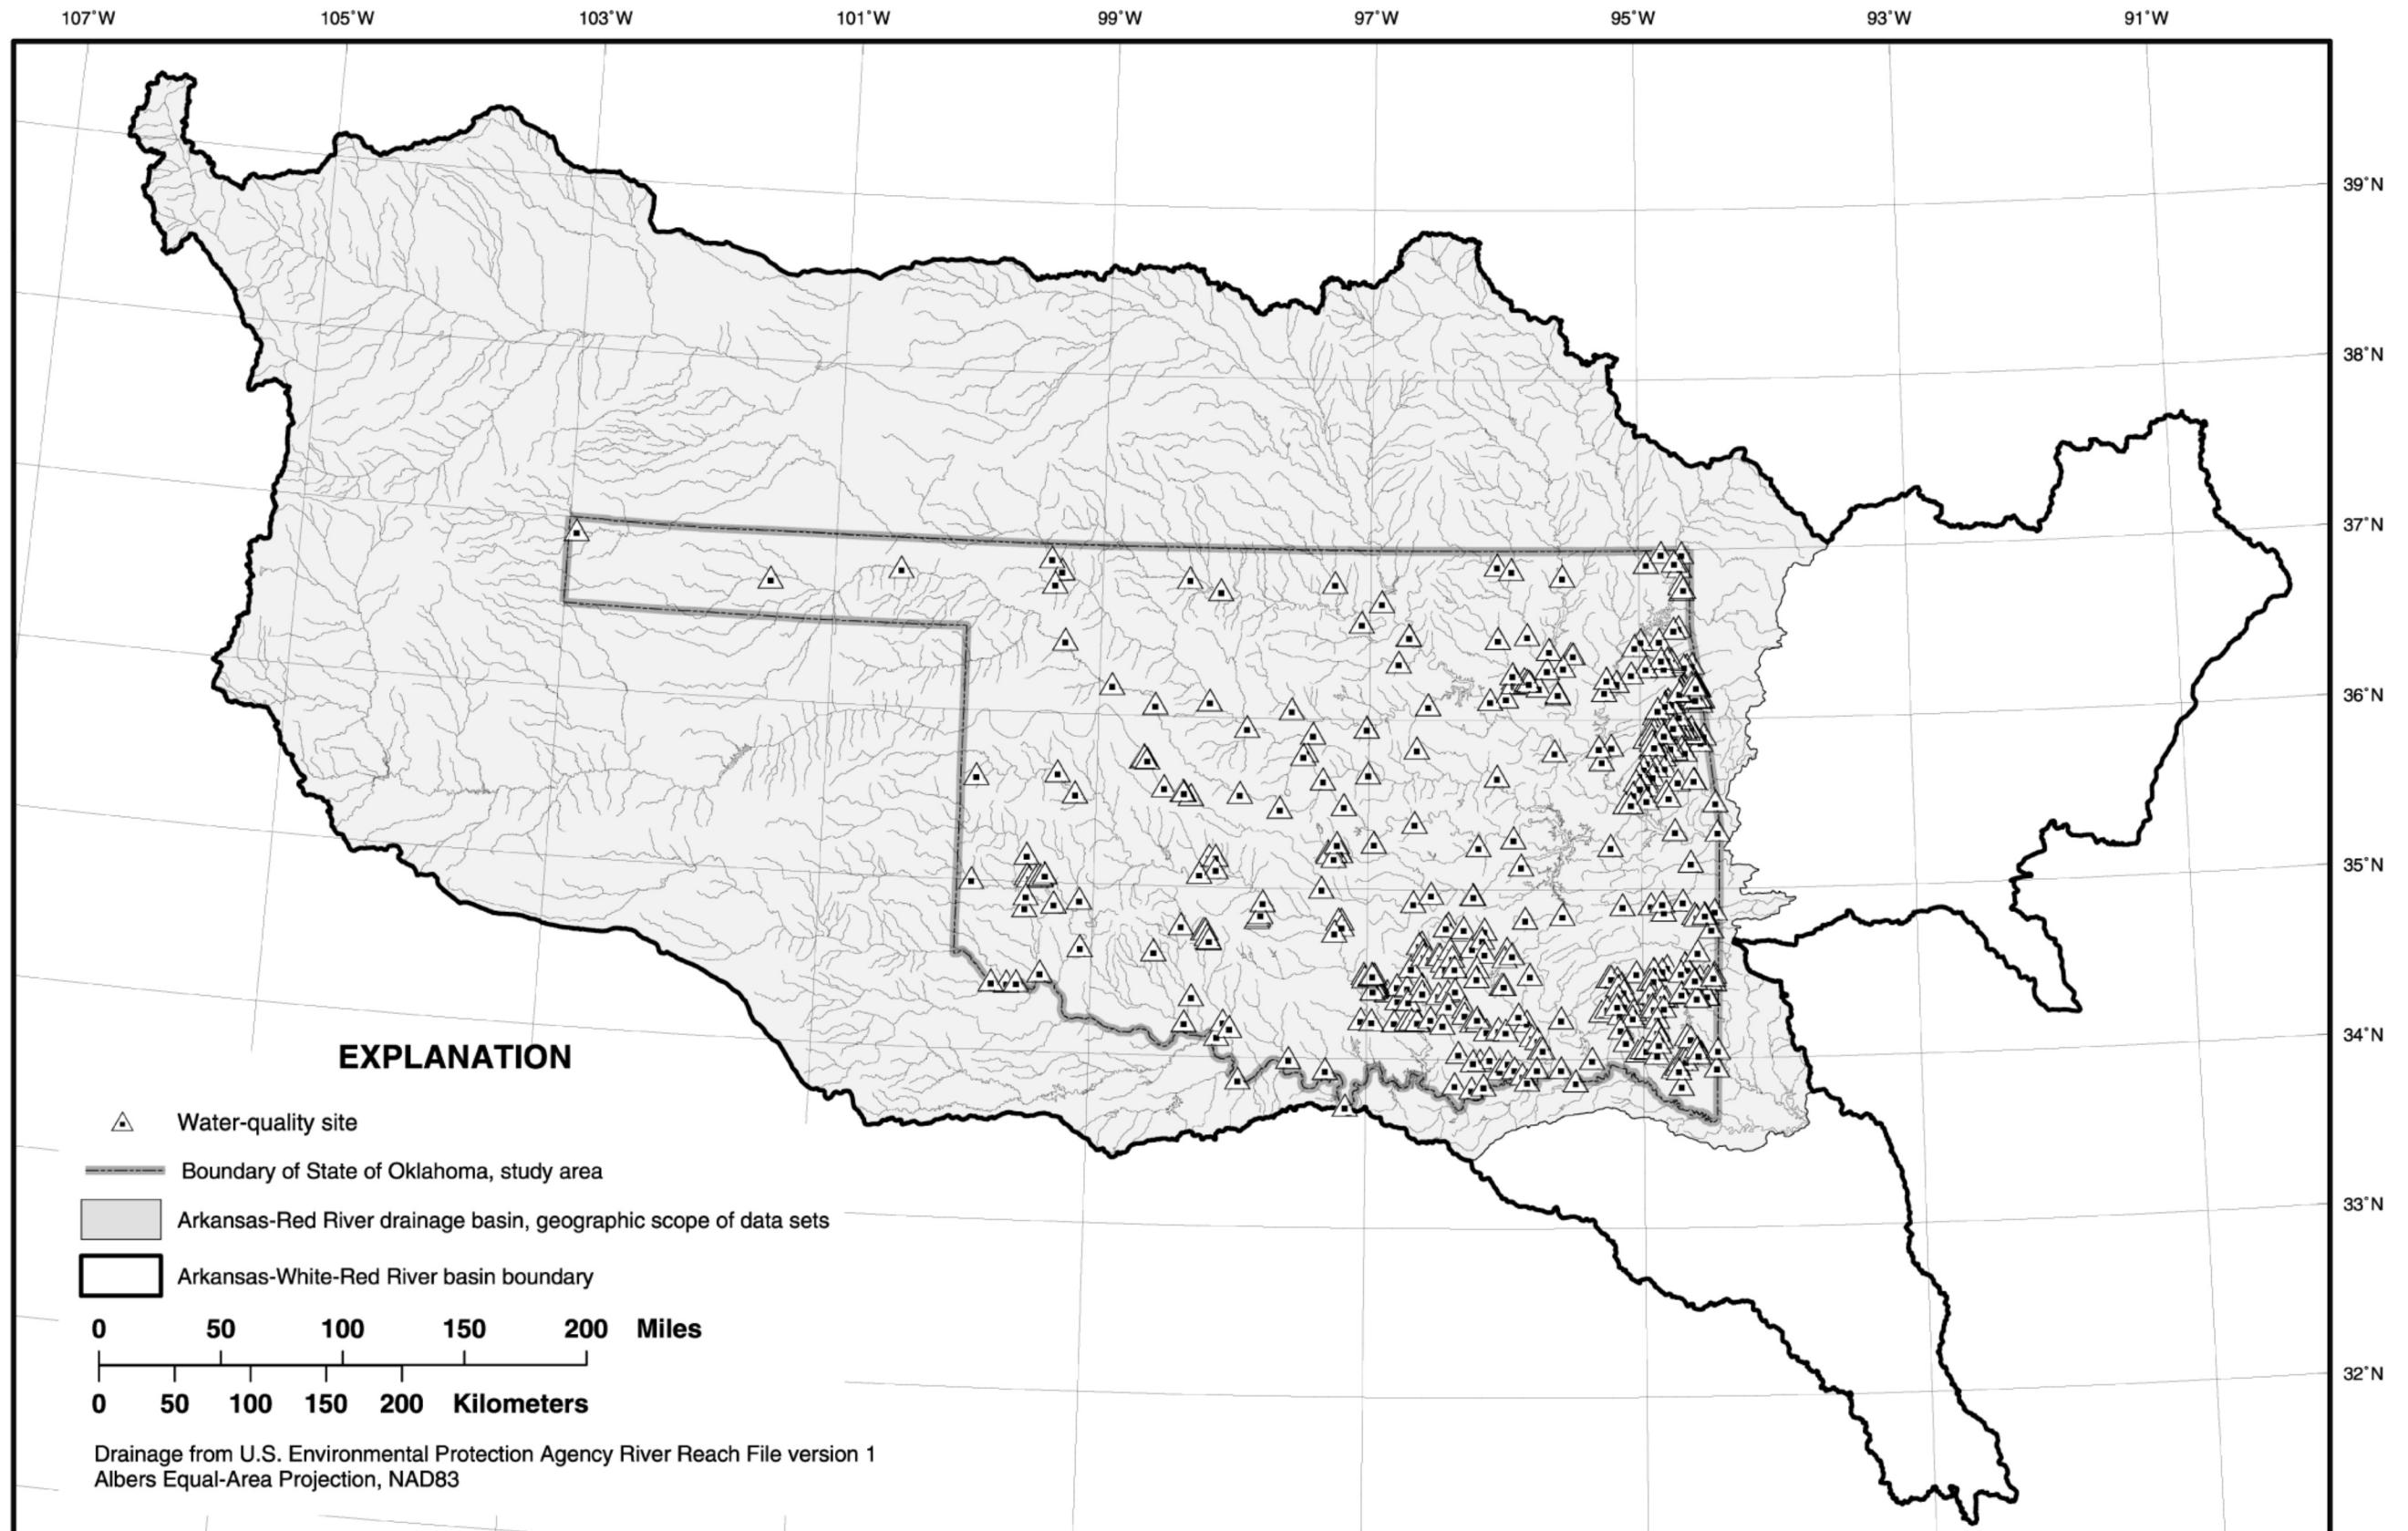

Figure 1. Locations of water-quality sites, study area, and geographic scope of data sets used to determine environmental characteristics.

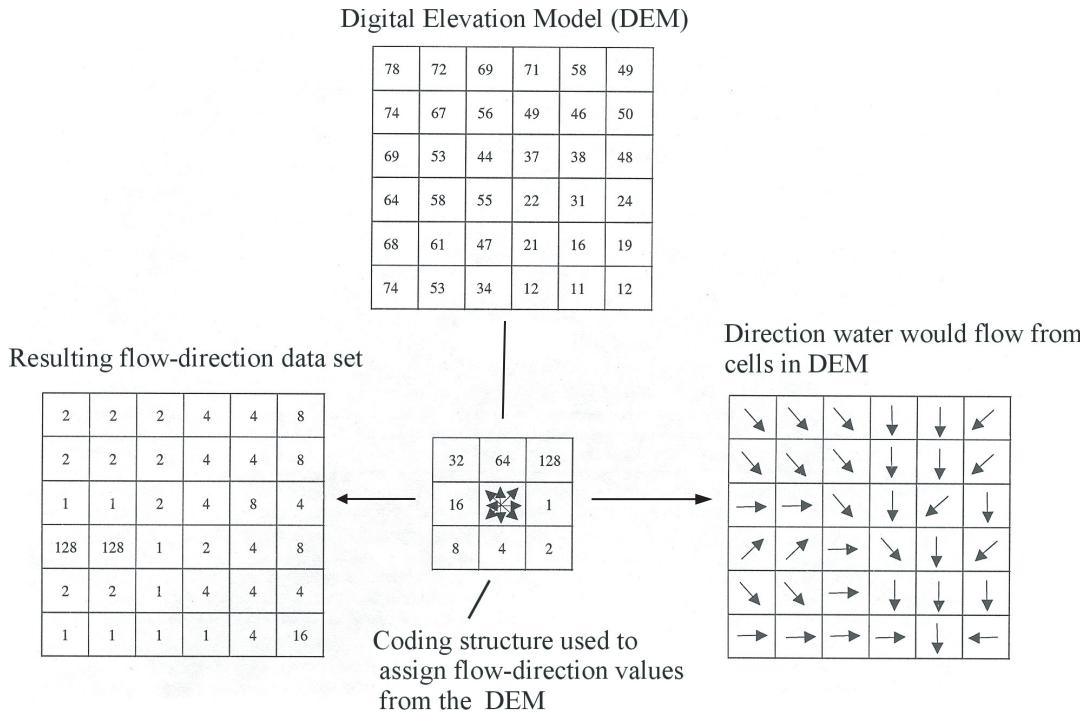

Figure 2. Flow-direction grid using a coding structure developed by Jenson and Domingue (1988), modified from Environmental Systems Research Institute (2001a).

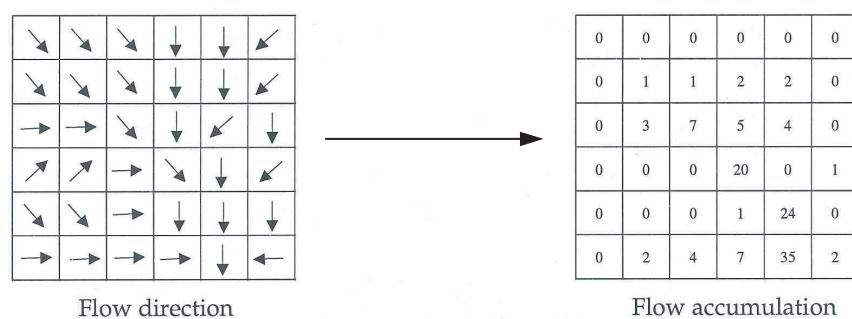

Figure 3. Flow-accumulation grid (modified from Environmental Systems Research Institute, 2001a).

6 Environmental Characteristics and Geographic Information System Applications for the Development of Nutrient Thresholds in Oklahoma Streams

seconds as units of measurement. NED is based on 1:24,000-scale topographic maps and has a resolution of one arc-second (equivalent to 30 meters). The NED data were projected to an Albers Equal Area projection and resampled to a 30-meter pixel resolution. Flow-direction and flow-accumulation data sets were created for the Arkansas-White-Red River basin (fig. 1) using the FILL, FLOWDIRECTION, and FLOWACCUMULATION functions (Elevation Derivatives for National Applications, 2001). These data sets (hydrologic derivatives of the NED) are similar to derivatives of the 60-meter DEM developed by Cederstrand and Rea (1995) used to delineate drainage basins.

The stream network needs to have a constant stream density and include all upstream headwaters to calculate stream order. Stream density can be expressed as a measure of closeness between stream channels. A stream network that varies in stream density will produce higher stream order values in more dense areas and lower stream order values in less dense areas. Figure 4 shows U.S. Geological Survey 1:100,000-scale topographic quadrangle boundaries and the National Hydrography Dataset (NHD) (2001). The varying stream density is shown in the upper Bristow quadrangle in relation to stream density in the lower Shawnee quadrangle. This variation in stream density is due to varying detail during the digitizing process.

A detailed and consistent stream network was created using the ARC/INFO GRID function STREAMLINE to convert the raster linear network (flow accumulation) to a vector linear network (synthetic hydrography) that represented

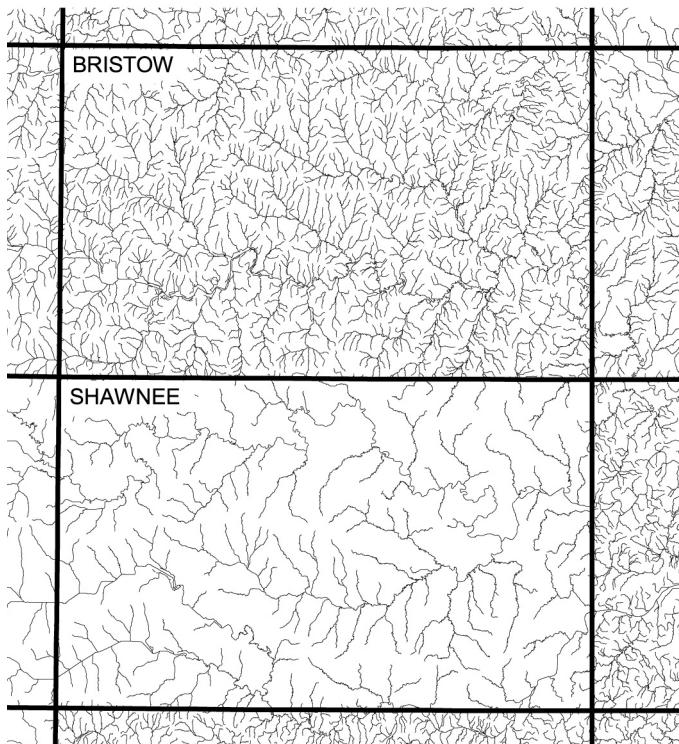

Figure 4. Portion of the National Hydrography Dataset (2001) in Oklahoma emphasizing the varying stream density.

streams at a consistent density (fig. 5). The synthetic hydrography data set was created using a threshold of 5,000 30-meter cells from the flow accumulation grid. Cell threshold has a direct affect on the length of headwater streams and minimum size of drainage-basin areas that can be delineated. The minimum size drainage basin that could be delineated based on a threshold of 5,000 30-meter cells is 1.7 square miles. Increasing or decreasing the cell threshold directly affects the length of the synthetic hydrography. Although the derived synthetic hydrography is based on 1:24,000-scale topographic maps, derived 1st order streams, in areas of low topographic relief, may actually be a 2nd order stream when manually determined using 1:24,000-scale topographic map. In areas of high topographic relief, stream order values derived using the synthetic hydrography were consistent with stream order values determined manually using 1:24,000-scale topographic maps.

A program was used to assign stream order values for streams in the synthetic hydrography data set using methods developed by Strahler (1957; fig. 6).

The beginning or headwater streams are designated as first-order streams. A second-order stream is formed when two first-order streams intersect; when two second-order streams intersect, a third-order stream is formed; and so forth. The ARC/INFO NEAR command was used to locate the stream nearest to a water-quality site and transfer the stream order value to the water-quality site. The derived stream order values were transferred to the environmental characteristic data set (appendix 1, back of report).

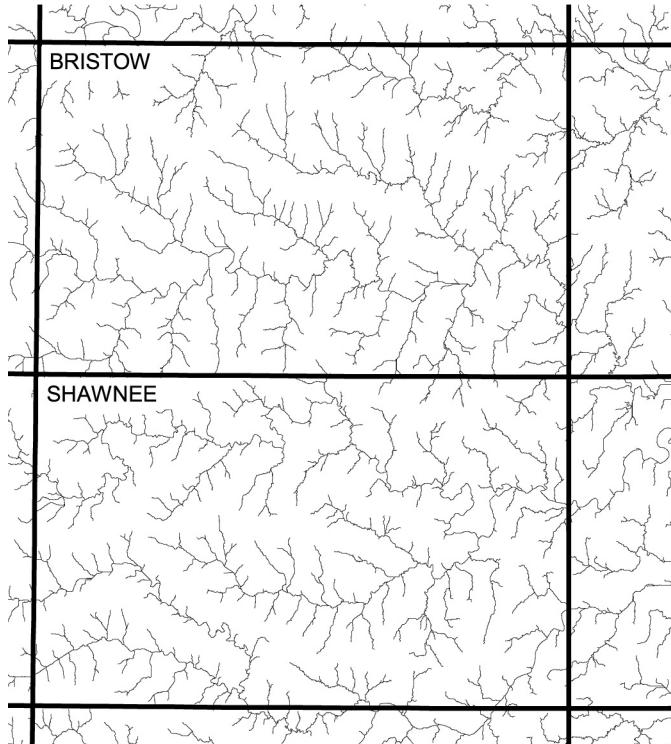

Figure 5. Synthetic hydrography created from the National Elevation Dataset (2001) showing the consistent stream density used to calculate stream order.

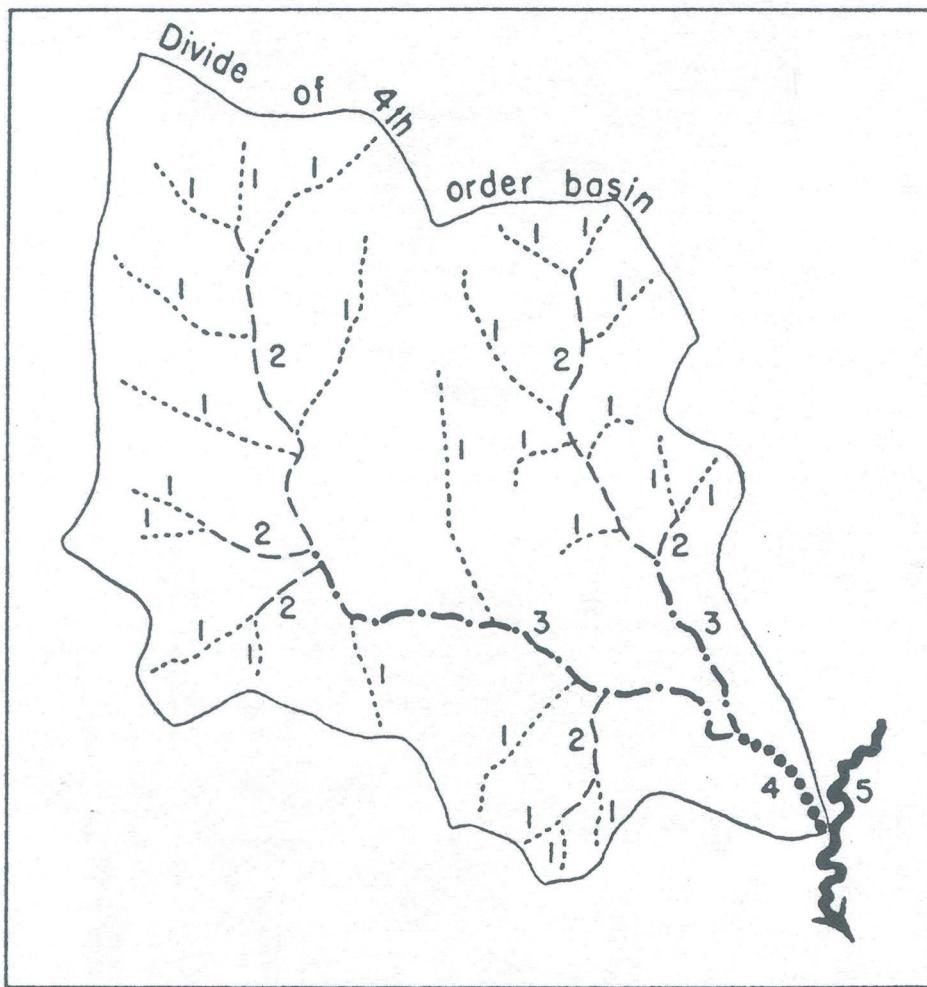

Figure 6. Method of designing stream order (modified from Strahler, 1957, p. 344).

Immediate Stream-Channel Slope

The immediate stream-channel slope is defined in this report as the change in elevation between beginning and ending points of a stream segment divided by the length of the stream segment. The average length of a stream segment used to compute the immediate stream-channel slope was 1.75 miles. The minimum and maximum lengths used were .31 mile and 3.1 miles, respectively. Stream slope varied slightly when checked against slope values determined manually from 1:24,000-scale topographic maps.

Basin characteristics such as stream slope can be problematic because the length measured is highly dependent on scale or in this case, dependent on the cell threshold used to create synthetic hydrography. Flow-accumulation data sets, and the DEM created by Cederstrand and Rea (1995) were used to calculate the immediate stream-channel slope for each of the 798 water-quality sites. The "Drainage-basin areas" section of this

report provides specific information about topographic data sets created by Cederstrand and Rea.

A vector linear network that represented Oklahoma streams was created from the flow-accumulation data set using the ARC/INFO GRID function STREAMLINE. The flow-accumulation and flow-direction data sets created by Cederstrand and Rea (1995) were designed specifically for defining watersheds; therefore, the corresponding stream network is very dense and file size is very large. To decrease file size and reduce processing times, the ARC/INFO BUFFER command was used to select only the streams within a 5,000-meter distance from the water-quality sites (fig. 7). This method decreased the number of arcs from 567,727 to 58,794 arcs.

The NODEPOINT command was used to create points for each node in the stream data set. A node is defined as the beginning or ending point of a line; therefore, any confluence of streams would be represented as a node. A unique identification code for each point was used that linked the points back to

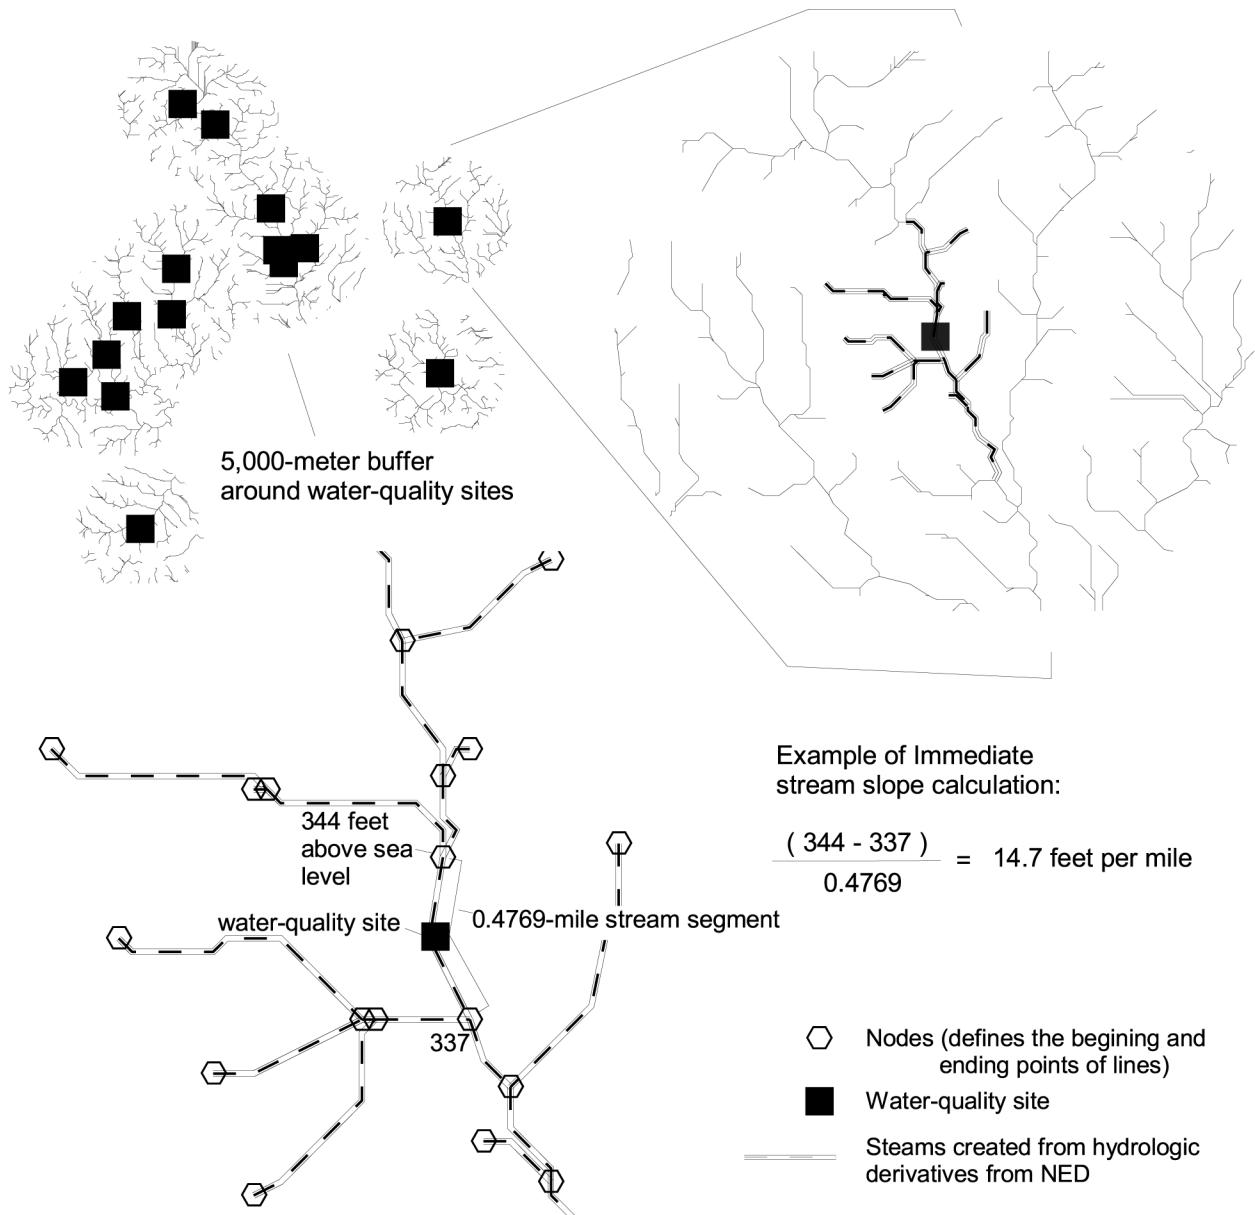

Figure 7. Method of designating immediate stream-channel slope.

the nodes in the stream data set. The LATTICESPOT command was used to overlay the point data onto the DEM and interpolate an elevation value from the underlying neighboring cells. The elevation values were transferred from the point data set to nodes in the stream data set using the RELATE and MOVE commands.

The CALCULATE command was used to compute the change in elevation between nodes, divided by the distance between nodes. This calculation resulted in the immediate stream-channel slope for stream segments near water-quality sites (fig. 7). The NEAR command was used to locate the nearest stream segment for each water-quality site and transfer the slope value to the water-quality data set. The stream slope values were transferred to the environmental characteristic data set (appendix 1, back of report).

Land Use

Land-use proportions were computed for each of the 798 drainage-basin areas using the ARC/INFO GRID module and land-use information from the National Land Cover Dataset (NLCD) (2000). The NLCD is based on 30-meter Landsat Thematic Mapper (TM) data acquired by the Multi-Resolution Land Characterization (MRLC) Consortium. The base data set for the NLCD project was compiled using leaves-off Landsat TM data, nominal-1992 acquisitions and other ancillary leaves-on Landsat TM data. The NLCD data set consists of 21 land-use categories (table 1). These land-use categories were aggregated to produce a land-use data set that consisted of 11 land-use categories (table 2).

A land-use data set was compiled for the Arkansas-White-Red River basin (fig.1). The ARC/INFO MASK command was used to clip out land-use information for each drainage basin. This method produced a land-use data set for each drainage area. Land-use proportions within each drainage basin were calculated by dividing the number of cells of a given category by the total number of cells in a drainage basin multiplied by 100 to yield the percent land-use. The land-use proportions were appended to the environmental characteristic data set (appendix 1, back of report).

Summary

The U.S. Environmental Protection Agency (USEPA) has developed nutrient criteria using ecoregions to manage and protect rivers and streams in the United States. Individual states and tribes are encouraged by the U.S. Environmental Protection Agency to modify or improve upon the ecoregion approach. The Oklahoma Water Resources Board (OWRB) has developed a dichotomous process that stratifies or groups streams based on environmental characteristics such as stream order and stream slope; this process is commonly known as the Use Support Assessment Protocols, subchapter 15 (USAP). The OWRB is using nutrient and environmental characteristic thresholds developed from a study conducted in the Netherlands. The U.S. Geological Survey, in cooperation with the OWRB, is providing descriptive statistics of water-quality sampling sites that can be used to modify the USAP to reflect hydrological and ecological conditions relevant to Oklahoma streams and rivers. Four environmental characteristics -- drainage-basin area, stream

slope, stream order, and land-use proportions -- that affect nutrient concentrations in Oklahoma streams were compiled using a Geographic Information System and are provided in appendix 1 (back of report).

Data sets of flow-direction and flow-accumulation (also referred to as hydrologic derivatives) were used to define drainage basins for 798 water-quality sites in Oklahoma. The ARC/INFO GRID module was used to create drainage basins and compute corresponding areas. Individual water-quality sites were used to define a pour point (an outlet for a drainage area) from which a complete or partial drainage basin was created. An automated process was developed that iteratively selected a water-quality site, converted it into a pour point, snapped the pour point to cells of high flow-accumulation, and delineated a drainage basin for that site. Over 400 drainage basins extended beyond the coverage of the flow-accumulation and flow-direction data sets developed by Cederstrand and Rea (1995). The ARC/VIEW GEOPROCESSING extension was used to append drainage partially defined drainage areas to the most detailed digital hydrologic unit maps available for those areas.

Stream order was calculated using methods developed by Strahler (1952) and a stream data set created from a hydrologic derivative (flow accumulation) of the U.S. Geological Survey National Elevation Dataset (NED). The stream data set derived from the flow accumulation dataset modeled streams in Oklahoma at a consistent stream density. A program was used to assign stream order values for streams in the synthetic hydrography data. The beginning or headwater streams are designated as a first-order stream. A second-order stream is formed when two first-order streams intersect; when two second-order streams intersect, a third-order stream is formed; and so forth.

The immediate stream-channel slope for each of the 798 water-quality sites was calculated using flow-accumulation and Digital Elevation Model data sets. A vector linear network that represented streams in Oklahoma at a consistent density was created from the flow-accumulation data set. A point data set was made from each beginning and ending node in the stream data set. A unique identification code was used that linked the point data set to the stream data set. The point data set was used to overlay the DEM and extract elevation information for each point. Elevations for each point were transferred to the nodes in the stream data set using unique identification codes. A simple calculation using the change in elevation between nodes, divided by the distance between nodes, was performed to calculate the immediate stream-channel slope for stream segments near water-quality sites.

Land-use proportions were computed for each of the 798 drainage-basin areas using the ARC/INFO GRID module and land-use information from the National Land Cover Dataset (NLCD). The NLCD is based on 30-meter Landsat Thematic Mapper (TM) data acquired by the Multi-Resolution Land Characterization (MRLC) Consortium. The base data set for the NLCD project was compiled using leaves-off Landsat TM data, nominal-1992 acquisitions and other ancillary leaves-on Landsat TM data. The NLCD data set consists of twenty-one land-use categories. These land-use categories were aggregated to produce a land-use data set that consisted of 11 land-use categories. A land-use data set was compiled for the Arkansas-White-Red River basin. Drainage-basin boundaries were used to select only the land-use information inside the drainage basins. Land-use proportions within each drainage basin were calculated by dividing the number of cells of given category by the total number of cells in a drainage basin multiplied by 100.
